Extracorporeal membrane oxygenation – a pump oxygenator performs gas exchange allows the lungs to be ‘rested’. Again, only available in specialist centres.

Summary
ARDS is diagnosed clinically on the basis of the acute development of hypoxaemic respiratory failure, CXR changes and non-cardiogenic pulmonary oedema, on the background of a pulmonary or non-pulmonary precipitating condition. ARDS may affect one in ten intensive care unit patients, and it carries a mortality of 30-40%.

Pathologically ARDS is characterised by an inflammatory phase involving neutrophils and cytokines, followed by a reparative process that may end in fibrosis.

Patients exhibit the signs and symptoms of pulmonary oedema, though features of the underlying condition may influence the picture.

Management consists of treating the underlying condition, providing support for failing systems and early invasive ventilation. Limiting the FiO₂ may help to prevent further lung damage, while limiting tidal volumes to 6-8ml/kg has been shown to reduce mortality. In cases of refractory hypoxaemia PC-IRV or ventilation in the prone position may improve blood gases, but have not been proven to influence survival. In addition there are many advanced techniques but many are only available in specialist centres, and none convincingly reduce mortality.

ASSESSMENT OF SPINAL ANAESTHETIC BLOCK

Graham Hocking, Sir Charles Gairdner Hospital, Perth, Western Australia.
Email: ghocking@btinternet.com

Spinal anaesthesia has the advantage that profound nerve block can be produced in a large part of the body by the relatively simple injection of a small amount of local anaesthetic. The practical technique has been described previously so will not be covered again in this article [see Update 12]. However, the greatest challenge in spinal anaesthesia is to control the spread of local anaesthetic through the cerebrospinal fluid (CSF) to provide a block which is adequate for the proposed surgery without unnecessary extensive spread, and increased risk of complications. This article will cover the assessment of spinal anaesthetic block. In an article in Update 23 the factors that influence how the local anaesthetic spreads within the CSF, determining the extent of the block, will be covered. Learning will be improved if you try to answer the questions posed throughout the text before continuing on to the next section.

Introduction
Studies of drug distribution usually involve measurements of concentration in a relevant body fluid compartment over time. However, multiple sampling of CSF at one level, let alone at the several needed to build an image of drug distribution through the theca, is impractical. Indirect indicators of spread are used based on tests of neurological response. Some indicator of the degree and extent of nerve block is needed before surgery can start.

| Before moving on, think about what methods you know to test the extent of spinal anaesthetic block? |
| What types of nerves are you studying for each test you can think of? |

Many methods may be used to test a block, but they fall broadly into one of two groups: assessment of either afferent (sensory), or efferent (motor or autonomic) function.

Afferent function
Pinprick and cold are most commonly used, but mechanical stimuli such as touch, skin pinch, pressure and gas jets can be used. Generally, loss of sensation to cold occurs before pinprick, and both of these before touch, each stage correlating with inhibition of C, Aδ and Aβ fibres respectively. Thus, temperature perception is lost before pinprick, is
generally at a higher level, and is usually assessed by
the application of ‘cold’ using alcohol skin prep, ice,
ethyl chloride, or a cold gel bag. Loss of vibration and
proprioceptive sensation have also been used.

More definitive assessment of pain sensation has been
attempted with tetanic stimulation using peripheral
nerve stimulators, and transcutaneous electrical
nerve stimulation, both of which correlate well with
surgical incision.

**Efferent function**

As a block extends cephalad, there is progressive
impairment of motor as well as sensory function. The
commonest method of assessment is the modified
‘Bromage scale’.

<table>
<thead>
<tr>
<th>Grade</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>No motor block</td>
</tr>
<tr>
<td>1</td>
<td>Inability to raise extended leg; able to move knees and feet</td>
</tr>
<tr>
<td>2</td>
<td>Inability to raise extended leg and move knee; able to move feet</td>
</tr>
<tr>
<td>3</td>
<td>Complete block of motor limb</td>
</tr>
</tbody>
</table>

This gives no more than a crude mix of information
on both the spread and degree of motor block in
the lumbo-sacral distribution. Complete inability
to straight leg raise (Bromage grade 3) implies the
spinal anaesthetic block has reached the high lumbar
segments and any surgery on the leg below the groin
should be able to proceed.

Thoracic nerve block paralyses the abdominal wall
and intercostal muscles, and can be quantified using
tests of pulmonary function. Although the effects are
proportional to height of block, they are too difficult
to test accurately to be used to identify the level
accurately.

Sympathetic block leads to cardiovascular changes.
Hypotension and bradycardia are related to block
height, but again do not accurately indicate the extent
of the block. Vasomotor responses can be used to
detect neuronal integrity, and can be detected by
colour and temperature changes in the affected area
but are less reliable signs and occur at a higher level
of block, than sensory changes.

**Which of the methods described do you think you
might be able to use on a regular basis?**

**Routine methods**

Experienced clinicians may use very little formal
testing, relying on early onset of lower limb weakness,
expected cardiovascular changes and altered
tsensation over the proposed site of surgery. This is
usually reliable as anaesthetists gain confidence after
repeated use of a technique.

Cold, most commonly applied as an ethyl chloride
spray, is popular, but usually defines a level of
block above the level of ‘surgical’ anaesthesia, and
ethyl chloride is an atmospheric pollutant. Ice and
alcoholic skin prep may be used as alternatives.
Gentle pinprick has the advantages of being simple,
repeatable, reproducible and applicable. It also allows
discrimination between ‘sharp’ and ‘dull’ sensation
and more closely indicates the level of ‘surgical’
aesthaesthesia. Pinprick testing should be performed
using a sterile needle which does not need to pierce
the skin and is compared to a non-anaesthetised part
of the body (eg arm) so the patient can perceive the
difference?

**I tested that the area of skin the surgeon planned to
cut through was numb using cold and pinprick but
the patient still got pain. Why did this happen?**

**Inadequacy of the test**

An apparently “adequate” spinal may fail because the
block has been tested using a stimulus of significantly
different modality or intensity than the planned
surgery. Pain during surgery can occur despite altered
sensation over the surgical site for a number of
reasons. A simple, single stimulus (e.g. pinprick, cold)
may be blocked, but only accurately tests responses
to that stimulus in the local area. Surgery involves
multiple forms of afferent stimulation and spinal cord
mechanisms may result in repeated stimuli (temporal
summation), or stimuli from adjacent regions (spatial
summation), evoking pain and leading to a “failed
block”. Intrathecal block is better than epidural at
inhibiting spatial summation and this partly explains
the more profound block produced. In addition,
demonstration of the segmental extent of block of
one modality does not enable accurate prediction of
any other. In general, however, loss of cold sensation
is observed at a higher dermatomal level than pinprick
which in turn is higher than the level at which touch
is lost, although there can be variation even in this
observation.

**Anatomical innervation**

When considering using regional anaesthesia for
surgery it is important to remember that the skin,
muscles, bones and organs all have different nerve
supplies. Just because the area of skin a surgeon
cuts through is numb, does not mean that everything
underneath is anaesthetized. This arises due to the
way the body develops and the spinal segmental
level of innervation for dermatomes (skin innervation),
myotomes (muscle innervation) and organ innervation
do not necessarily coincide. These deep sensations
are important to keep in mind. A good example to
illustrate this is when the dentist is working on your
teeth under local anaesthesia. You can often be numb
for pain but the sensation of deep pressure can still be very uncomfortable. This is often the sensation people get despite “good” superficial blocks. Either the spinal anaesthesia has to be extensive enough to block the sensations from deep structures or the patient warned they may experience some sensation of pressure during the procedure.

Can you think of an operation where this is very obvious?

When does checking the level of skin numbness mislead?

During caesarian section, although the skin cut usually occurs as a low midline incision (T12/L1), the structures underneath have spinal segmental innervations much higher. The uterus is innervated by T10 and the peritoneum has innervations as high as T4. This is why a patient should ideally be numb up as far as her nipple line (T4-5) if she is to not feel pain during this operation. The same principle is true of other operations within the abdomen. Since peritoneal innervation may not be completely blocked in some patients, it is important to warn them that they will often still feel something happening (sometimes felt as pressure) although it should not be painful. A gentle surgeon will be able to help minimize this.

Operations on the lower limbs do not tend to suffer from this problem in the clinical setting.

The diagram gives a guide to the level of spinal dermatomes and the level required for anaesthesia of some of the abdominal organs.

Summary

1. Decide on the highest level of innervation that will need to be blocked for the proposed surgery remembering that the underlying organs and peritoneum may come from higher spinal segments.
2. Check for lower limb weakness as an early indicator that the injection was correct. Inability to straight leg raise suggests the block will cover at least all the lumbar segments.
3. Cold can be used but will usually demonstrate blocked segments higher than those with surgical anaesthesia. Pinprick will generally be closer to the level of surgical anaesthesia.
4. To be completely happy that surgery can be performed painlessly it is wise to ensure that the level of testing to cold or pinprick is at least 2-3 segments higher than that needed. This will provide a margin for error and also ensure that the operative site does not regain sensation too quickly.

Before leaving this article, make sure you can answer the questions below.

Questions

1. What types of nerves are tested by cold, pinprick and touch?
2. Is the sensation of cold sensation lost above or below the level that pain could be felt on surgical incision?
3. What test is the best predictor of whether an area is numb enough to be cut?
4. Why is the anaesthesia from a spinal block more profound than with an epidural?
5. What level of spinal segmental innervation are the uterus, bladder, appendix and peritoneum?

The answers can all be found in the text of this article.
